The B lymphocyte response to HIV was examined in seronegative homosexual men at high and low risk for AIDS. Clonal analysis revealed that over half of these subjects had B cells that were part of a large, clonal population. This clonality was not related to the HIV antibody status of the subjects. All of the subjects had the B cell phenotype indicative of polyclonal activation; this was the case whether or not the subjects were HIV-seropositive. Thus, polyclonal activation of B cells appears to be an early response to a lifetime exposure to HIV. B cells were activated with the same B cell receptor (BCR) specificity as T cells. The clonal analysis reveals that only one of the 13 B cell clones is associated with a higher BCR affinity (Kd). This one BCR was found more frequently in the group of patients with increased HIV antibody titers, and was therefore the basis for the increased susceptibility of these individuals to HIV infection. The B cells of individuals at low risk for AIDS do not reveal evidence of clonal maturation, whereas the B cells of patients with AIDS-related complex and AIDS have an activated B cell phenotype. These results suggest that other factors are needed to allow the evolution of high-affinity B cells in the bone marrow of patients with AIDS. Linker Histone H1.5 on the X Chromosome Provides Full Compensation for the Loss of the Other Linker Histone, H1.4. The inner core of higher eukaryotic chromatin is built by histone octamers, which are composed of two copies of each core histone H2A, H2B, H3, and H4, and two copies of linker histone H1. Linker histones have been studied extensively for their unique ability to compact and bundle DNA. In addition, recent evidence has shown that linker histones have other functions independent of their ability to condense DNA, including a role in recruiting chromatin remodeling activities. Here we used the conditional gene-knockout strategy to study the roles of H1 linker histones H1.5 and H1.4 in vivo. We
